Osteoblastoma of the Sternum
Case Report and Review of the Literature

Abstract

Osteoblastoma is an extremely rare entity that represents less than 1% of all bone tumors, and affects twice as many males as females with peak incidence between 15 and 20 years. Osteoblastomas commonly affect axial bones, long bones, bones of the foot and hand, and less commonly the pelvis, scapula, ribs, and clavicle. Osteoblastoma does not have a classic presentation, but can vary with the location and size of the tumor. The main complaint is often progressive pain localized at the tumor site. Osteoblastoma is a benign tumor with an aggressive behavior. The treatment is wide surgical resection, otherwise it continues to enlarge and destroy the bone and surrounding structures. We report a 32-year-old male with an osteoblastoma of the sternum who was treated with an en-bloc resection and reconstruction with Marlex® and a methylmethacrylate plate.

Osteoblastoma is a rare, benign primary tumor of bone. There have been only three cases of osteoblastoma in the sternum reported in the literature. The current case report is of a benign osteoblastoma in the sternum of a 32-year-old male. Tumors arising from the bones of the chest wall are uncommon, but, when they occur, they are usually malignant. Initially described by Jaffe, in 1932, and later, again, by Jaffe and Lichtenstein, in 1956, osteoblastoma also was known as giant osteoid osteoma, as its histology resembled that of an osteoid osteoma. Osteoblastoma affects twice as many males as females and has a peak incidence in patients between 15 and 20 years of age; 90% of cases are diagnosed before the age 30. Osteoblastoma commonly affects the vertebral column; long bones, such as the femur and tibia; and also the foot and hand. Less commonly, the pelvis, scapula, ribs, and clavicle are sites. Osteoblastoma is a benign entity but sometimes demonstrates aggressive growth; however, it can be differentiated radiologically and histologically from osteosarcoma. We report the clinical presentation, radiologic and pathologic findings, and surgical and medical management, with a review of the literature.

Case Report

A 32-year-old male presented with a mass in the region of his left sternoclavicular joint. He complained of swelling in the area for 5 months prior to his consultation. The mass was mildly painful and had progressively increased in size. He experienced chest pain at night, which would awaken him from sleep and was only partially relieved by nonsteroidal antiinflammatory medication. There was no history of fever, though he did complain of occasional night sweats and some weight loss. There was no parasesthesia, except in his left upper extremity. His past medical history was significant for asthma. He had no history of infections, intravenous drug abuse, tuberculosis, or malignancy. He never had had surgery. His mother had a history of breast cancer; otherwise, there was no further significant family history.

On physical examination, the patient had a very firm and immobile mass (approximately, 5 cm) over his manubrium and left sternoclavicular joint, with mild tenderness on palpation. He had full range of motion throughout his left upper limb.
No motor or sensory deficits were noted in the extremities bilaterally. Pulses and reflexes were normal. Blood work, including complete blood count, chemistries, coagulation analysis, erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) were all normal.

Plain radiographs of the chest were interpreted as normal. Axial (Fig. 1A) and coronally reconstructed (Fig. 1B) computed tomography (CT) images demonstrated a large geographic lobulated lesion involving the left side of the manubrium. The lesion was expansile, extending into the overlying ventral soft tissues, as well as posteriorly into the mediastinum. The soft tissue component was surrounded by a rim of reactive bone. Faint areas of internal mineralization were noted. No periosteal reaction was identified. The lesion measured approximately 4x3.3x4.4 cm. On magnetic resonance imaging (MRI), the lesion demonstrated a lobular configuration with slight heterogeneity. The lesion was predominantly isointense to muscle, with a hyperintense central signal and a thin surrounding rim of low signal on axial (Fig. 2A) and sagittal (Fig. 2B) T1-weighted images. On axial T2-weighted images (Fig. 2C), the lesion also was heterogeneous, but predominantly hyperintense in signal, with mild surrounding soft tissue edema. The lesion demonstrated uptake on bone scan, with no evidence of multicentric or metastatic disease.

The patient underwent a CT-guided biopsy. Multiple cores of soft tissue were obtained from the lesion. Pathological analysis revealed an osteoblastoma. The pectoralis major was sutured to the edges of the rectus abdominis muscle. There were no intraoperative or postoperative complications.

The entire specimen measured 10.5x9x5.5 cm. The tissue had a red-tan appearance and gritty consistency. The cut gross section revealed a well demarcated mass in the sternum measuring 4.5x3.7x3.8 cm. Histological examination revealed a bone-forming tumor, composed of anastomosing immature bone trabeculae, surrounded by a rim of osteoblasts, and separated by a fibrovascular stroma. There were variable amounts of osteoid and bone. Some osteoblasts showed atypical changes. The mitotic activity was low. The margins of the host bone-tumor interface were sharp, and well circumscribed. There was no evidence of tumor permeation. The above histologic features were consistent with osteoblastoma (Fig. 4).

There have been no complications or complaints related to the reconstruction after 3 years postoperatively. The patient is pain free and has full function of both upper extremities. He has no respiratory problems, and he exercises without shortness of breath.

**Discussion**

Osteoblastoma is a rare, benign primary bone tumor, likely related to osteoid osteoma. Initially, it was described by Jaffe and Mayer,1 in 1932, under the descriptive name of “An osteoblastic osteoid tissue-forming tumor of a metacarpal bone.” Later, both Jaffe2 and Lichtenstein,3 in 1956, and Lichtenstein and Sawyer,4 in 1964, described osteoblastoma in various articles under the title “Benign osteoblastoma.” Osteoblastomas are rare and represent less than 1% of all bone tumors and approximately 3.5% of all benign bone tumors.5,7

In Osteoblastoma, males are affected more often than females, with a respective ratio of 2:1. Most patients are between 15 and 20 years of age and approximately 90% of cases are diagnosed before the age of 30.6,7 The mean age at presentation in the largest series studied was 20.4 years, with
wide range from 6 months to 75 years. Osteoblastoma occurs four-times less frequently than osteoid osteoma. There is a predilection for the axial skeleton, particularly the posterior elements of the vertebral column. The next most common site is the long bones of the extremities, although it also has been reported in the hands, feet, skull, maxilla, scapula, clavicle, and ribs. Osteoblastomas usually arise from the medullary cavity of the bones; periosteal origin is rare. There have been only three cases reported in the literature of osteoblastoma in the sternum: two in adults and one in a child.

Osteoblastoma does not have a specific clinical presentation. The presentation varies with the location and size of the tumor. The main complaint is often progressive pain, localized at the tumor site. It is often a dull aching pain, sometimes worst at night and is not relieved with salicylates, as with osteoid osteomas. The affected bone may be expanded and appear as a palpable mass, associated with tenderness and swelling. The lower extremity may cause gait problems. Patients with an osteoblastoma localized in the vertebral column may complain of radiating pain, tingling, weakness, paresthesias, and even paraplegia. Sometimes, osteoblastomas may be asymptomatic and are diagnosed incidentally.

Radiologic studies are useful in establishing the diagnosis. Plain radiographs may vary according to the stage of tumor at the time of presentation. Generally, the lesions appear as well-defined expansile radiolucent lesions, sometimes associated with delicate, thin internal trabeculae and a rim of surrounding sclerosis. Osteoblastomas may demonstrate subtle internal calcifications, but mineralization is generally not detectable on plain radiograph. There also may be sur-

Figure 2 A, An axial T1-weighted MRI demonstrates the lesion to be predominantly isointense to the surrounding muscle with a linear low signal periphery and internal septations. B, A sagittal T1-weighted image further demonstrates the relationship of the mass to the surrounding soft tissue structures. C, An axial T2-weighted MRI demonstrates the lesion to be lobular with central areas of high signal and a low signal rim. There is suggestion of surrounding soft tissue edema.

rounding periosteal new bone formation.\textsuperscript{2,5} The size of an osteoblastoma is usually greater than 2 cm and can range from 2 to 8 cm. This is generally larger than the presentation of an osteoid osteoma.\textsuperscript{2,5,9} Lucas and colleagues\textsuperscript{8} reported on 306 cases of osteoblastoma, in which the size ranged from 1 to 11 cm, with a mean of 3.2 cm.

CT scans can provide useful information regarding the size, precise location, and any soft tissue extension of the lesion. This may be particularly useful with spinal lesions. CT scans may also delineate the presence of subtle mineralization; thus, aiding in diagnosis, as well as providing information necessary for the planning of a surgical procedure. Osteoblastomas demonstrate increased uptake on a bone scan. Bone scans are useful to localize the lesion and detect multicentric lesions, but have limited resolution in some cases.\textsuperscript{5}

MRI is helpful for determining intraosseous and soft tissues extension and in terms of vertebral tumors and encroachment on the spinal cord and neural elements.\textsuperscript{5,15} Kroon and Schumars\textsuperscript{16} and Cervoni and coworkers\textsuperscript{15} described low to intermediate signal intensity on T1-weighted images and high signal intensity on T2-weighted images. The degree of enhancement on post Gadolinium images also has been variably reported from none to strong enhancement.\textsuperscript{15} Thus, there does not appear to be a specific, characteristic appearance of osteoblastoma with MRI.

The pathological features of osteoblastomas are similar to osteoid osteoma. Both are bone producing lesions that arise from osteoblastic origin. Osteoblastomas are larger than osteoid osteomas and appear to have unlimited growth potential. Usually, the lesion is reddish-brown, even pinkish; friable, with a gritty consistency; and hemorrhagic in appearance.\textsuperscript{2,4,9,14} The cortex is frequently thinned and expanded.\textsuperscript{9} Osteoblastomas are highly vascularized and sometimes can show secondary aneurysmal bone cyst formation.\textsuperscript{8,10} The osteoblast cells are often plump and pleomorphic. The nuclei vary from small to big, and there is usually abundant cytoplasm. The osteoblasts are responsible for osteoid formation and usually are arranged in an orderly manner, within a lining of primitive trabecular bone (osteoblastic rimming).\textsuperscript{6} The absence of dysplastic changes, and mitoses, as well as the orderly arrangement of normal appearing osteoblasts, are important features that help distinguish osteoblastoma from osteosarcoma.\textsuperscript{14} The pathology should always be interpreted after careful review of the radiological studies.

There have been some cases of osteoblastomas reported to behave more aggressively. These tumors have been associated with large epithelioid osteoblasts. These “aggressive osteoblastomas” are more mitotically active than conventional osteoblastoma.\textsuperscript{8,14} Malignant degeneration has been reported, although it is speculative as to the initial nature of the lesion. At long-term follow-up (10 years), Jackson reported 10% recurrence after incomplete resection.\textsuperscript{17} Marsh and associates\textsuperscript{10} and Lucas and colleagues\textsuperscript{8} collected 197 and 305 cases, respectively, and reported local recurrence in 16% to 21% of cases. The size, location, and ability to resect the entire lesion are important factors related to recurrence, morbidity, and mortality, although metastasis has been rarely documented.\textsuperscript{8,14}

The natural history of osteoblastomas when they are not excised surgically is to continue to enlarge and damage the bone and adjacent structures. They are benign and aggressive in nature. Therefore, the treatment of an osteoblastoma is wide surgical resection. Whenever feasible, spine lesions should be removed en bloc. Extensive curettage of long bone lesions may be possible in most cases. Postoperative radiation is usually not recommended; however, it may be considered for tumors that have recurred multiple times, particularly around the spine.

The tumor, in this case, was treated with wide en bloc resection, because it was extending into the surrounding soft tissues and was close to vital structures in the mediastinum. We believe that this approach provided the best surgical treatment for minimizing the chance of a local recurrence in this critical region. The sternum was reconstructed with a plate of methylmethacrylate that was sandwiched between two

layers of Marlex® mesh. The ribs and clavicles were sutured to the mesh and a rectus abdominus rotational muscle flap was employed to cover the prosthesis. The patient is 4-years postoperative. He is pain free and has no functional limitations and no respiratory difficulties.

Many techniques have been described for the closure of chest wall defects to minimize paradoxical movement of the chest and protect underlying mediastinal structures after sternal resection. Since 1972, Marlex® mesh filled with methylmethacrylate was utilized for complete sternectomy reconstruction, providing excellent stability and cosmetic acceptability.18,19 Chapelien and coworkers20 reported 38 who patients underwent sternal reconstruction. They found that Marlex® mesh alone (without methylmethacrylate) was sufficient for reconstruction following partial sternectomy.21,22 Marlex® mesh filled with methylmethacrylate has been recommended following total sternectomy to limit paradoxical chest motion.21 Soysal and associates22 recommended muscle flaps in cases with upper partial sternectomy (manubrium with ribs 1 to 3) and rigid reconstructions (mesh with methylmethacrylate) for cases with lower sternal resections to protect the heart and stabilize the thorax. This has also been proposed by several other authors.19-21

Muscle or myocutaneous flaps are frequently used to repair defects of the chest wall alone or in conjunction with rigid replacements.19,20 The most common muscle flaps used are the latissimus dorsi, pectoralis major, rectus abdominis, serratus anterior, external oblique, trapezius.19 Omental muscle replacements.19,20 The most common muscle flaps used are muscle or myocutaneous flaps are frequently used to repair previously failed muscle flaps.19 Omental muscle flaps are often used for infected sternal wounds or in cases of other authors.19-21

Osteoblastomas are challenging for the physician to diagnose and manage. They should be biopsied carefully to provide enough material to make an accurate diagnosis. High quality imaging studies aid in the diagnosis and surgical planning, and should be correlated with histological material to ensure an accurate diagnosis. Osteoblastomas are characterized by both benignity and aggressive behavior, with a propensity for local destruction and recurrence. There have been a few reported cases presenting in the sternum. Surgery is the mainstay of treatment, with the type of surgery depending on the tumor’s size and anatomic location. En bloc resection is recommended for lesions of the sternum that expand or violate the cortex.
